This paper considers trial-offer markets where consumer preferences are modelled by a multinomial logit
with social influence and position bias. The social signal for a product is given by its current market share
raised to power r (or, equivalently, the number of purchases raised to the power of r). The paper shows
that, when r is strictly between 0 and 1, and a static position assignment (e.g., a quality ranking) is
used, the market converges to a unique equilibrium where the market shares depend only on product
quality, not their initial appeals or the early dynamics. When r is greater than 1, the market becomes
unpredictable. In many cases, the market goes to a monopoly for some product: which product becomes a
monopoly depends on the initial conditions of the market. These theoretical results are complemented by
an agent-based simulation which indicates that convergence is fast when r is between 0 and 1, and that
the quality ranking dominates the well-known popularity ranking in terms of market efficiency. These
results shed a new light on the role of social influence which is often blamed for unpredictability, in-
equalities, and inefficiencies in markets. In contrast, this paper shows that, with a proper social signal
and position assignment for the products, the market becomes predictable, and inequalities and ineffi-
ciencies can be controlled appropriately.

1. Introduction

The impact of social influence and product visibilities on consumer behaviour in Trial-Offer (T-O) markets1
has been explored in a variety of settings (e.g., Salganik, Dodds, & Watts, 2006; Tucker &
Zhang, 2011; Viglia, Furlan, & Guevara, 2014). Social influence can be dispensed through different types of social signals: a market
place may report the number of past purchases of a product, its consumer ratings, and/or its consumer recommendations. Recent
studies Engstrom and Forsell (2014), Viglia et al. (2014) however
came to the conclusion that the popularity signal (i.e., the number
of past purchases or the market share) has a much stronger impact on
consumer behaviour than the average consumer rating signal.2

These two experimental studies were conducted in very different
settings, using the Android application platform in one case and
hotel selection in the other. Consumer preferences are also influ-
enced by product visibilities, a phenomenon that has been widely
observed in internet advertisement (e.g., Craswell, Zoeter, Taylor, &
Ramsey, 2008), in online stores such as EXPEDIA, AMAZON, and iTUNES, as well as physical retail stores (see, e.g., Lim, Rodrigues, &
Zhang, 2004).

Despite its widespread use in online settings (including for
songs, albums, movies, hotels, and cell phones to name only a few),
there is considerable debate in the scientific community about the
benefits of social influence. Many researchers have pointed out
the potential negative effects of social influence. The seminal work
of Salganik et al. (2006) on the MusicLab experimental market
demonstrated that social influence can introduce significant unpre-
dictability, inequality, and inefficiency in T-O markets. These results
were reproduced by many researchers (e.g., Muchnik, Aral, &
Taylor, 2013; van de Rijt, Kang, Restivo, & Patil, 2014; Salganik
& Watts, 2008; 2009). More recently, Hu, Milner, and
Wu (2015) studied a newsvendor problem with two substitutable
products with the same quality in which consumer preferences are

2 A trial-offer market is a setting where consumers can try products before de-

ciding whether to buy them or not.

The music market iTUNES shows the normalised market share of each song of
an album.
affected by past purchases. The authors showed that the market is unpredictable but can become less so if one of products has an initial advantage. Altszyler, Berbeglia, Berbeglia, and Van Hentenryck (2017) has recently studied the impact of product appeal and product quality in a trial-offer market model with social influence under a finite time horizon. The authors showed that there exists a logarithmic tradeoff between the two: the final product market share remains constant if a decrease in product quality is followed by an exponential increase in the product appeal. Other researchers have focused on understanding when these undesirable side-effects arise and where they come from. Ceyhan, Mousavi, and Saberi (2011) studied a market specified by a logit model where a constant \( J \) captures the strength of the social signal. They showed that the market behaviour (e.g., whether it is predictable) depends on the strength of the social signal. Their results did not consider product visibilities, which is another important aspect of T-O markets. Indeed, various researchers (e.g., Abeliuk, Berbeglia, Cebrian, & Hentenryck, 2015; 2016; Abeliuk, Berbeglia, Hentenryck, Hogg, & Lerman, 2017; Hentenryck, Abeliuk, Berbeglia, Berbeglia, & Maldonado, 2016; Lerman & Hogg, 2014) indicated that unpredictability and inefficiencies often depend on how products are displayed in the market. In particular, Abeliuk et al. (2015) show that social influence is always beneficial in expectation when the products are ordered by the performance ranking that maximises the purchases greedily at each step. This result was obtained using the generalised multinomial logit model proposed by Krumme, Cebrian, Pickard, and Pentland (2012) to reproduce the MusicLab experiments. Hentenryck et al. (2016) proves a similar result for the quality ranking that assigns the highest quality products to the most visible positions. In addition, they show that the market converges to a monopoly for the highest quality product. These results contrast with the MusicLab experiments which relied on the popularity ranking that dynamically assigns the most popular products to the most visible positions.

This paper seeks to expand our understanding of social influence in T-O markets and explores the role of the social signal in conjunction with product visibilities. Our starting point is the generalised multinomial logit model of Krumme et al. (2012), which we extend to vary the strength of the social signal. More precisely, this paper considers a T-O market where the probability of purchasing product \( i \) at time \( t \) is given by

\[
p_i(\mathbf{q}) = \frac{v_{r(i)} q_i(\mathbf{q})^r}{\sum_{j=1}^n v_{r(j)} q_j(\mathbf{q})^r},
\]

where \( \sigma \) is a bijection from \( n \) products to \( n \) positions, \( v_k \in \mathbb{R} \) is the visibility of position \( k \), \( q_i \in \mathbb{R} \) is the inherent quality of product \( i \), \( \phi_i \) is the market share of product \( i \) at time \( t \), and \( r > 0 \) is the strength of the social signal. As should be clear from the discussion above, prior work on T-O markets with product visibilities (e.g., Abeliuk et al., 2015; Abeliuk, Berbeglia, Maldonado et al., 2016; Hentenryck et al., 2016; Lerman & Hogg, 2014) focused on the case of a linear social signal (\( r = 1 \)). The primary objective of this paper is to understand what happens to the T-O market when \( r < 1 \).

The paper contains both theoretical and simulation results and its contributions can be summarised as follows:

1. When \( r < 1 \) and a static ranking is used, the market converges to a unique equilibrium, which we characterise analytically. In the equilibrium, the market shares depend only on the product qualities \( q_i \) and no monopoly occurs. Moreover, a product of higher quality receives a larger market share than a product of lower quality, introducing a notion of fairness in the market and reducing the inequalities introduced by a linear social signal.

2. When \( r > 1 \) and a static ranking is used, the equilibria can be characterised similarly. However, contrary to the case \( r < 1 \), the equilibria that are not monopolies can be shown to be unstable under certain conditions. As a result, the market will typically go to a monopoly for some product: which product wins the entire market share depends on the initial condition and the early dynamics.

3. Agent-based simulations show that the market converges quickly towards an equilibrium when using sublinear social signals and the quality ranking. They also show that the quality ranking outperforms the popularity ranking in maximising the efficiency of the market. The popularity ranking is also shown to have some significant drawbacks in some settings.

These theoretical results indicate that, when the social influence signal is a sublinear function of the market share and a static ranking of the products (e.g., the quality ranking) is used, the market is entirely predictable, depends only on the product quality, and does not lead to a monopoly. This contrasts with the case of \( r = 1 \) where the market is entirely predictable but goes to a monopoly for the product of highest quality (assuming the quality ranking) (Hentenryck et al., 2016) and the case of \( r > 1 \) where the market becomes unpredictable (even with a static ranking). As a result, sublinear social signals provide a way to balance market efficiency and the inequalities introduced by social influence. In particular, with sublinear social signals and a static ranking, markets do not exhibit a Matthew effect where the winner takes all, and remain predictable.

The remaining of this paper is organised as follows. Section 2 describes the related work. Section 3 introduces T-O markets and the generalised multinomial logit model for consumer preferences considered here. Section 4 reviews some necessary mathematical preliminaries, including the fact that T-O markets can be modelled as Robbins–Monro algorithms. Section 5 derives the equilibria for the market as a function of the social signal and also presents the convergence results. Section 6 reports the results from the agent-based simulation. Section 7 discusses some additional results on sublinear signals. Section 8 discusses the results and concludes the paper.

2. Related work

The research presented in this paper was motivated by the seminal work of Salganik et al. (2006). They study an experimental market called the MusicLab, where participants were presented a list of unknown songs from unknown bands, each song being described by its name and band. The participants were partitioned into two groups exposed to two different experimental conditions: the independent condition and the social influence condition. In the independent group, participants were shown the songs in a random order and they were allowed to listen to a song and then to download it if they so wish. In the second group (social influence condition), participants were shown the songs in popularity order, i.e., by assigning the most popular songs to the most visible positions. Moreover, these participants were also shown a social signal given by the number of times each song was downloaded. In order to investigate the impact of social influence, participants in the second group were distributed in eight “worlds” evolving completely independently. In particular, participants in one world had no visibility about the downloads and the rankings in the other worlds. The MusicLab exemplifies a T-O market where each song represents a product, and listening and downloading a song represent trying and purchasing a product respectively. The results in Salganik et al. (2006) show that different worlds evolve differently from one another, and significantly so, providing evidence that social influence may introduce unpredictability, inequalities, and inefficiency in the market.
The results in Salganik et al. (2006) were reproduced by numerous researchers (e.g., Muchnik et al., 2013; van de Rijt et al., 2014; Salganik & Watts, 2008; 2009) and, in particular, by Krumme et al. (2012) who model the MusicLab experiment with a generalised multinomial logit where product utilities depend on the song appeal, quality, visibility, and a social influence signal representing past purchases. The T-O market studied in this paper generalises the model proposed by Krumme et al., exploring various strengths for the social signal as indicated in Eq. (1). The case of a linear signal \( r = 1 \) has been given significant attention. Abeliuk et al. (2015) proposed the performance ranking which orders the products optimally at each time \( t \) given the appeals, qualities, visibilities, and market shares. They show that, when the performance ranking is used, the market always benefits from social influence in expectation. Hentenryck et al. (2016) study the quality ranking which ranks the products by quality: they show that the quality ranking and, more generally, any static ranking, always benefits from social influence in expectation. They also prove that the market converges almost surely to a monopoly for the highest-quality product, indicating that the quality ranking is both optimal and predictable asymptotically. These results extend well-known theorems on Pólya urns and their generalisations (e.g., Chung, Handjani, & Jurisic, 2003; Mahmoud, 2008; Renlund, 2010). Abeliuk, Berbeglia, Cebrian, and Hentenryck (2016) also show that the performance ranking converges to a monopoly for the highest-quality product when a linear social signal is used.

Ceyhan et al. (2011) study a general choice probability \( C_j(\phi) \), where \( J \) represents the strength of the social signal, and prove some general convergence results under some assumptions. In particular, they use the ODE method (Ljung, 1977) and a Lyapunov function (e.g., Kushner & Yin, 2003) to prove that the market converges to an equilibrium when the Jacobian of \( C_j \) is symmetric (which is not the case when product visibilities are present). They also study in detail the case where the market follows a logit model of the form

\[
C_j(\phi) = \frac{e^{\phi_i + \phi_j}}{\sum_{t} e^{\phi_t + \phi_j}},
\]

where \( J \) is a constant capturing the strength of the social influence signal. They show that there exists a parameter \( J^* \) such that the market converges toward a unique equilibrium when \( J < J^* \) and to a monopoly when \( J > J^* \). No analytical characterisation of the equilibrium when \( J < J^* \) is presented.

It is interesting to contrast these and our results. Observe first that the proof technique used in Ceyhan et al. (2011) relies on the fact that the Jacobian of \( C_j \) is symmetric, which is not the case for T-O markets with product visibilities. Our paper studies such T-O markets and show that, when \( 0 < r < 1 \) and a static ranking is used, the market converges to an inner equilibrium, which we characterise analytically. When \( r = 1 \), the T-O market converges to a monopoly for the product with the highest value \( v_{\sigma(i)}(J) \) (Abeliuk et al., 2015). When \( r > 1 \), we show that the equilibria of the T-O market are given by monopoles for each product and other type of equilibria (e.g., a market share consisting on a distribution 60%, 40%, 0% for a market with 3 products). We prove that, when \( r > 1 \), the equilibria that are not monopoles are unstable (under certain conditions). As a result, the market will likely converge to a monopoly for some product.

It is also useful to mention that different, theoretical and experimental, approaches to the use of social influence are present in the literature. For instance, Yuan and Hwang (2016) describe a demand-based pricing model under social influence and capture its behaviour with a dynamical system that evolve to some stable or chaotic equilibria depending on the strength of the social signal. Stummer, Kiesling, Günther, and Vetschera (2015) introduces an agent-based model for repeat purchase decisions addressing different types of innovation diffusion and their perceived attributes; They also applied this methodology to an application concerned with second-generation biofuel.

### 3. The trial-offer model

The paper builds on the work by Krumme et al. (2012) who propose a framework in which consumer choices are captured by a multinomial logit model whose product utilities depend on the product appeal, position bias, and a social influence signal representing past purchases. A marketplace consists of a set \( N \) of \( n \) items. Each item \( i \in N \) is characterised by two values:

1. its appeal \( a_i > 0 \) which represents the inherent preference of trying item \( i \);
2. its quality \( q_i > 0 \) which represents the conditional probability of purchasing item \( i \) given that it was tried.

This paper assumes that the appeals and the qualities are known. Abeliuk et al. (2015) have shown that these values can be recovered accurately and quickly, either before or during the market execution using the approximation suggested by Krumme et al.:

\[
a_i \sim \frac{s_i}{J} \sum_{j} s_j
\]

and

\[
q_i \sim \frac{d_i}{s_i}
\]

where \( s_i \) and \( d_i \) are the samplings and purchases of product \( i \) at some point in time, respectively.

The objective of the firm running this market is to maximise the total expected number of purchases. To achieve this, the key managerial decision of the firm is what is known as the ranking policy (Abeliuk et al., 2015), which consists in deciding how to display the products in the market (e.g., where to display a product on a web page). Here we assume that, at the beginning of the market, the firm decides upon a ranking for the items, i.e., an assignment of items to positions in the marketplace. Each position \( j \) has a visibility \( v_j \) which represents the inherent probability of trying an item in position \( j \). A ranking \( \sigma \) is a permutation of the items and \( \sigma(i) = j \) means that item \( i \) is placed in position \( j (j \in N) \).

When a customer enters the market, she observes all the items and their social signals based on the values of the previous purchases \( d^t = (d^t_1, \ldots, d^t_n) \).

The vector \( \phi^t \) of market shares at time \( t \) is computed in terms of the vector \( d^t \), i.e.,

\[
\phi^t = \frac{d^t_1}{\sum_{j=1}^n d^t_j}.
\]

and

\[
\phi^t \in \Delta^{n-1} = \{x = (x_1, \ldots, x_n) \in \mathbb{R}^n \mid 0 \leq x_1 \leq 1 \text{ and } \sum_{i=1}^n x_i = 1\}.
\]

The consumer then selects an item to try. The probability that the customer tries item \( i \) is given by \( P_i(\sigma, \phi^t) \) where

\[
P_i(\sigma, \phi) = \frac{v_{\sigma(i)}(J)f(\phi_j)}{\sum_{j=1}^n v_{\sigma(j)}(J)f(\phi_j)}
\]

and \( f \) is a continuous, positive, and nondecreasing function. This probability generalises the multinomial logit model of Krumme et al. (2012) who define two sets of probabilities, \( p_{ii}^t \) and \( p_{ij}^t \), that capture the probability of trying product \( i \) with and without social influence. These probabilities are defined as:

\[
p_{ii}^t = \frac{v_{\sigma(i)}(\alpha a_i + d^t_i)}{\sum_{j=1}^n v_{\sigma(j)}(\alpha a_j + d^t_j)} \quad p_{ij}^t = \frac{v_{\sigma(i)}(a_i)}{\sum_{j=1}^n v_{\sigma(j)}a_j}.
\]
where \( \alpha \) is a parameter to calibrate the strength of the social signal (e.g., \( \alpha = 200 \) for the MusicLab experiments). Eq. (2) allows us to recover the formulae (3) via some linear transformation of the identity function: \( f(\phi_i) = \beta \phi_i + \alpha \psi_i \), with \( \beta = \sum d_j \) or \( \beta = 0 \) for each case.

After having tried product \( i \), a customer decides whether to buy the sampled item and the probability that she purchases item \( i \) is given by \( q_i \). If item \( i \) is purchased at time \( t \), then the purchase vector becomes

\[
d_{i}^{t+1} = \begin{cases} d_{i}^{t} + 1 & \text{if } j = i; \\ d_{i}^{t} & \text{otherwise}. \end{cases}
\]

For simplicity, the vector \( \mathbf{d}_t \) is initialised with the product appeals, i.e., \( d_{i}^{0} = q_{i} \). This condition can be relaxed and the results presented in this paper continue to hold but the notations are heavier (see Appendix C for the details). To analyse this process, we divide time into discrete periods such that each new period begins when a product has been purchased. Hence, the length of each time period is not constant.

In this paper, we are interested in characterising how the market shares \( \{\phi_{i}\}_{i=0}^{n} \) evolve over time for various functions \( f \) given a static ranking \( \sigma \). We are particularly interested in study the asymptotic behaviour of \( \{\phi_{i}\}_{i=0}^{n} \) for the cases where \( f(x) = x^{r} \) with \( r > 0 \). For instance, when \( r = 0.5 \), the social signal displays the square root of the number of past purchases. For notational simplicity, we assume that the ranking is fixed and is the identity function \( \sigma(i) = i \) and omit it from the formulæ. If the qualities and visibilities also satisfy \( q_{1} \geq \cdots \geq q_{n} \) and \( v_{1} \geq \cdots \geq v_{n} \), we obtain the quality ranking proposed in Hentenryck et al. (2016) but our results hold for any static ranking.

The following lemma, whose proof is in Appendix B, relates the two phases of the T-O market and characterises the probability that the next purchase is item \( i \). It generalises a result in Hentenryck et al. (2016).

**Lemma 3.1.** If \( f : [0, 1] \rightarrow \mathbb{R} \) is a positive function, then the probability \( p_{i}(\phi) \) that the next purchase is the product \( i \) given the market share vector \( \phi \) is given by

\[
p_{i}(\phi) = \frac{v_{i}q_{i}f(\phi_{i})}{\sum_{j=1}^{d_{i}} v_{j}q_{j}f(\phi_{j})}.
\]

This section concludes with an important equivalence which is valid when \( f(x) = x^{r} \), \( r > 0 \); Eq. (4) remains the same when expressed in terms of the number of purchases \( d_{i} \) instead of the market shares. Indeed,

\[
p_{i}(\phi) = \frac{v_{i}q_{i}(\phi_{i})^{r}}{\sum_{j=1}^{d_{i}} v_{j}q_{j}(\phi_{j})^{r}} = \frac{v_{i}q_{i}(\sum_{j=1}^{d_{i}} v_{j}q_{j})^{r}}{\sum_{j=1}^{d_{i}} v_{j}q_{j}(\sum_{j=1}^{d_{i}} v_{j}q_{j})^{r}} = \frac{v_{i}q_{i}(d_{i})^{r}}{\sum_{j=1}^{d_{i}} v_{j}q_{j}(d_{j})^{r}}
\]

Hence, when the social signal function is \( f(x) = x^{r} \), \( r > 0 \), our model can be interpreted either using the concept of market share or simply the number of purchases.

### 4. Trial-offer markets as Robbins–Monro algorithms

This section establishes some basic definitions and concepts that are useful in the rest of the paper. In particular, it shows that T-O markets can be modelled as Robbins–Monro algorithms and states some useful results. The results in this section are well-known in stochastic approximation. The section starts with a brief introduction of Ordinary Differential Equations (ODE) and some

---

3 The initialisation can be justified by viewing the discrete dynamic process as an urn and balls process, where the appeals are the initial sets of balls.

4 In Section 6, we modify the notion of time period to stabilise the efficiency of trial-offer markets.

---

**Differential equations.** Consider the following differential equation

\[
\frac{dy}{dt} = F(y)
\]

where \( F \) is some vector field. The concept of equilibrium is central in the study of asymptotic behaviour for this type of equation.

**Definition 4.1.** A vector \( y^{*} \in \mathbb{R}^{n} \) is an equilibrium for differential equation (6) if \( F(y^{*}) = 0 \).

We are interested in equilibria that satisfy (at least) certain stability criteria.

**Definition 4.2.** An equilibrium \( y^{*} \) is said to be stable for Eq. (6) if, given \( \epsilon > 0 \), there exists \( \delta > 0 \) such that \( \| y(t) - y^{*} \| < \epsilon \) for all \( t > 0 \) and for all \( y \) such that \( \| y - y^{*} \| < \delta \). We say that \( y^{*} \) is asymptotically stable if it also satisfies

\[
\lim_{t \to \infty} y(t) = y^{*}.
\]

**Remark 4.3.** When an equilibrium \( y^{*} \) is not stable, we say that \( y^{*} \) is unstable.

The asymptotic stability of an equilibrium \( y^{*} \) can be characterised in terms of the Jacobian matrix \( F(y^{*}) \). We now show that the discrete stochastic process \( \{\phi_{i}\}_{i=0}^{n} \) can be modelled as a Robbins–Monro Algorithm (RMA) (Duflo & Wilson, 1997; Kushner & Yin, 2003).\(^5\)

**Theorem 4.4.** Let \( y^{*} \) be an equilibrium for the differential equation (6). If the eigenvalues of the Jacobian matrix \( F(y^{*}) \) all have negative real part, then \( y^{*} \) is asymptotically stable. If, on the other hand, \( F(y^{*}) \) has at least one eigenvalue with a positive real part, then \( y^{*} \) is unstable.

A well-known result from linear algebra (see, for example, Robinson, 2006, p. 296) establishes the connection between the trace of a square matrix and its eigenvalues. In the following, we use \( tr(A) = \sum_{i=1}^{n} a_{ii} \) to denote the trace of matrix \( A \) where \( a_{ii} \) are the diagonal entries of matrix \( A \).

**Theorem 4.5.** Let \( A \) be an \( n \times n \) matrix, and \( \lambda_{1}, \ldots, \lambda_{n} \) its eigenvalues. Then \( tr(A) = \sum_{i=1}^{n} \lambda_{ii} \).

We now show that the discrete stochastic process \( \{\phi_{i}\}_{i=0}^{n} \) can be modelled as a Robbins–Monro Algorithm (RMA) (Duflo & Wilson, 1997; Kushner & Yin, 2003).

**Definition 4.6 (Robbins–Monro algorithm).** A Robbins–Monro algorithm (RMA) is a discrete time stochastic processes \( \{x_{k}\}_{k=0}^{\infty} \) whose general structure is specified by

\[
x_{k+1} - x_{k} = \gamma^{k+1}[F(x_{k}) + U^{k+1}],
\]

where

- \( \gamma^{k} \) takes its values in some Euclidean space (e.g., \( \mathbb{R}^{n} \));
- \( \gamma^{k} \) is deterministic and satisfies \( \gamma^{k} > 0 \), \( \sum_{k=1}^{\infty} \gamma^{k} = \infty \), and \( \lim_{k \to \infty} \gamma^{k} = 0 \);
- \( F : \mathbb{R}^{n} \rightarrow \mathbb{R}^{n} \) is a deterministic continuous vector field;
- \( \mathbb{E}[U^{k+1}x_{k}^{k+1}] = 0 \), where \( \mathbb{F} \) is the natural filtration of the entire process.\(^5\)

A RMA \( \{x_{k}\}_{k=0}^{\infty} \) where \( x_{k} \) has \( n \) coordinates is said to be \( n \)-dimensional. Recall that the probability that the next purchase is item \( i \) at time \( k \) is given by \( p_{i}(\phi_{k}) \) and denote by \( \phi_{k} \) the random

---

5 \( \mathbb{F} \), the natural filtration, is the \( \sigma \)-field generated by the history \( \{x_{t} : t \leq k\} \).
unit vector whose jth entry is 1 if item j is the next purchase and 0 otherwise. The market share at time $k+1$ is given by

$$\phi_{k+1} = \frac{D_k \phi_k}{D_k + 1} + \frac{e^k}{D_k + 1}$$

where $D_k = \sum_{i=0}^{k} \sum_{i=1}^{n} d_i = k + k_0$, where $k_0 = \sum_{i=1}^{n} a_i$. It follows that

$$\phi_{k+1} = \left(\frac{D_k + 1}{D_k + 1}\right)\phi_k - \frac{\phi_k}{D_k + 1} + \frac{e^k}{D_k + 1}$$

$$= \phi_k + \frac{1}{D_k + 1}(\phi_k - e^k)$$

$$= \phi_k + \frac{1}{D_k + 1}\left((p(\phi_k) - \phi_k + e^k - \mathbb{E}[x^k|F^k])\right)$$

$$= \phi_k + \frac{1}{D_k + 1}(p(\phi_k) - \phi_k + e^k - \mathbb{E}[x^k|F^k])$$

This last equality can be reformulated as

$$\phi_{k+1} = \phi_k + \gamma^{k+1}(F(\phi_k) + U_{k+1})$$

where $\gamma^{k+1} = \frac{1}{D_k + 1}$, $F(\phi) = p(\phi) - \phi$, and $U_{k+1} = e^k - \mathbb{E}[x^k|F^k]$. Note that the function $F$ captures the difference between the probabilities of purchasing the items (given the market shares) and the market shares at each time step. Recall that $\phi^k \in \Delta^{n-1}$ for all $k \geq 0$, which is a compact, convex subset of $\mathbb{R}^n$ (and hence connected). We can now prove that the discrete dynamic process $\{\phi^k\}_{k \geq 0}$ can be modelled as a Robbins–Monro algorithm.

**Theorem 4.7.** The discrete stochastic dynamic process $\{\phi^k\}_{k \geq 0}$ can be modelled as a Robbins–Monro algorithm.

**Proof.** The above derivation showed that $\{\phi^k\}_{k \geq 0}$ can be expressed through Eq. (8), i.e.,

$$\phi_{k+1} = \phi_k + \gamma^{k+1}(F(\phi_k) + U_{k+1})$$

where $\gamma^{k+1} = \frac{1}{D_k + 1}$, $F(\phi) = p(\phi) - \phi$, and $U_{k+1} = e^k - \mathbb{E}[x^k|F^k]$. It is easy to see that $\gamma > 0$, $\sum_{k \geq 1} \gamma^k = \infty$, $\lim_{k \to \infty} \gamma^k = 0$, and that $\mathbb{E}[U_{k+1}|F^k]$ is equal to zero. □

Robbins–Monro algorithms are particularly interesting because, under certain conditions on $x^k$, $y^k$, and $U_{k+1}$, their asymptotic behaviour, i.e., the values of $x^k$ when $k \to \infty$, is closely related to the asymptotic behaviour of the following continuous dynamic process:

$$dx^t = F(x^t), \quad x^t \in \Delta^{n-1}.$$  \hspace{1cm} (9)

This idea, called the ODE method, was introduced by Ljung (1977) and has been extensively studied (e.g., Borkar & Meyn, 2000; Duflo & Wilson, 1997; Kushner & Yin, 2003). Consider again the RMA $\{x^k\}_{k \geq 0}$ defined in (7) and the following hypotheses:

**H1:** sup $\mathbb{E}[\|U_{k+1}\|^2] < \infty$;

**H2:** $\sum_k (\gamma^k)^2 < \infty$;

**H3:** sup $\|x^k\| < \infty$.

We will now present a theorem establishing the connection between the discrete stochastic process (7) and the continuous process defined by (9). This connection requires the concept of Internally Chain Transitivity (ICT) sets. These ICT sets include equilibria, periodic orbits of (9), and possibly more complicated sets.

To define ICT sets formally for the purpose of this paper, we use Proposition 5.3 in Benaim (1999) that proves that the concepts of internally chain recurrent and internally chain transitive set are equivalent when the set over which $F$ is defined is connected, which is obviously the case here.

**Definition 4.8** ([ε, T)-chains, Conley, 1978]. Consider $\epsilon > 0$, $T > 0$, a set $A \subset \mathbb{R}^n$, and two points $x, y \in A$. There is an $(\epsilon, T)$-chain of length $k$ in $A$ between $x$ and $y$ if there exist $k$ solutions $\{y_i, \ldots, y_k\}$ of (9) and their associated times $\{t_1, \ldots, t_k\}$ with $t_i > T$ such that

1. $y_i \in A$ for all $i \in [0, t_i]$ and for all $i \in \{1, \ldots, k\}$;
2. $\|y_i - y_{i+1}\| < \epsilon$ for all $i \in \{1, \ldots, k - 1\}$;
3. $\|y_0 - x\| < \epsilon$ and $\|y_k - y\| < \epsilon$.

We are now in a position to define ICT sets, which is derived from the definition of Internally Chain Recurrent sets introduced by Conley (1978).

**Definition 4.9** (ICT sets). A closed set $A$ is said Internally Chain Transitive (ICT) for the dynamics (9) if it is compact, connected, and for all $\epsilon > 0$, $T > 0$ and $x, y \in A$, there exists an $(\epsilon, T)$-chain in $A$ between $x$ and $y$.

The following theorem, due to Benaim (1999) and whose proof is in Appendix B, links the behaviour of the limit set $L(x^k)_{k \geq 0}$ of any sample path $\{x^k\}_{k \geq 0}$ for Eq. (7) and the limit sets of the solution to Eq. (9).

**Theorem 4.10** (Benaim, 1999). Let $\{x^k\}_{k \geq 0}$ be a Robbins–Monro algorithm (7) satisfying hypotheses H1 – H3 where $F$ is a bounded locally Lipschitz vector field (e.g., a bounded c1 function). Then, with probability 1, the limit set $L(x^k)_{k \geq 0}$ is internally chain transitive for Eq. (9).

Note that Theorem 4.10 is valid for very general functions $F(x) = p(x) - x$, as the only requirement is to be locally Lipschitz. Since hypotheses H1, H2, and H3 are all satisfied by the discrete stochastic dynamic process $\{\phi^k\}_{k \geq 0}$, it remains to study the structure of the ICT set of Eq. (9). This paper focuses on the case where the social signal $x$ is given by $f(x) = x^r$, with $r > 0$. We will show that the ICT set of Eq. (9) only consists of equilibria.

### 5. Equilibria of trial-offer markets

This section characterises the equilibria and the asymptotic behaviour of the continuous dynamics

$$\frac{dd^t}{dt} = p(d^t) - d^t, \quad (d^t \in \Delta^{n-1}).$$  \hspace{1cm} (10)

which is associated with the RMA (8). For simplicity, we remove the possibilities by stating $q_i = p_i q_j$. We are interested in the case where $f(x) = x^r$ with $(r > 0, r \neq 1)$, since the case $r = 1$ has been settled in earlier work. Let $Q$ be the set of positive market shares, this is, $Q = \{i \in N : \phi_i \neq 0\}$. Clearly $Q \neq \emptyset$ since $\sum_{j=1}^{n} \phi_j = 1$.

**Theorem 5.1.** Let $f(x) = x^r, r > 0$, and $r \neq 1$. Any equilibria $\phi$ for Eq. (10) has coordinates

$$\phi_i = \frac{\bar{q}_i^{1/r}}{\sum_{j=0}^{Q} \bar{q}_j^{1/r}} \quad \text{if} \quad i \in Q$$

and zero otherwise (i.e., if $i \notin Q$).

**Proof.** An equilibrium to (10) must satisfy $p_i(\phi) = \phi_i$, i.e.,

$$\sum_{k=0}^{Q} \bar{q}_j(\phi_i)^r = \phi_i.$$

For $i \in Q$, we have

$$\bar{q}_i(\phi_i)^{r-1} = \sum_{j=0}^{Q} \bar{q}_j(\phi_j)^r$$

and, for all $i, k \in Q$, we also have

$$\bar{q}_i(\phi_i)^{r-1} = \sum_{j=0}^{Q} \bar{q}_j(\phi_j)^{r-1}.$$
which is equivalent to
\[
\bar{q}_i(\phi_i)^{-1} = \bar{q}_k(\phi_k)^{-1} \Leftrightarrow \phi_i = \left(\frac{\bar{q}_i}{\bar{q}_k}\right)^{\frac{1}{r}} \phi_k.
\] (11)

By summing for all \(i \in Q\), we obtain
\[
1 = \sum_{i \in Q} \phi_i = \frac{\phi_k}{\bar{q}_k^{1/(1-r)}} \sum_{i \in Q} q_i^{1/(1-r)}
\]
and hence
\[
\phi_k = \frac{\sum_{i \in Q} q_i^{1/(1-r)}}{\sum_{i \in Q} q_i^{1/(1-r)}} = \frac{\bar{q}_k^{1/(1-r)}}{\sum_{i \in Q} q_i^{1/(1-r)}}.
\]

It remains to prove \(\phi\) is indeed an equilibrium, i.e., \(p(\phi) = \phi\). This is equivalent to prove that \(p_j(\phi) = \phi_i\) for all \(i \in \{1, \ldots, n\}\). The result is obvious if \(i \in N/Q (\phi_i = 0 \Rightarrow p_i(\phi) = 0)\). If \(i \in Q\), then
\[
p_i(\phi) = \frac{\bar{q}_i(\phi_i)^r}{\sum_{j \in Q} \bar{q}_j(\phi_j)^r} = \frac{1}{\sum_{j \in Q} \bar{q}_j(\phi_j)^r} \left(\sum_{j \in Q} \bar{q}_j^{1/(1-r)}\right)^r \left(\sum_{j \in Q} \bar{q}_j^{1/(1-r)}\right)^{-r} = \frac{\bar{q}_i^{1/(1-r)}}{\sum_{j \in Q} \bar{q}_j^{1/(1-r)}} = \phi_i.
\]

Note that, when \(|Q| = n\), the equilibrium lives in the interior of the simplex \(\int(\Delta^{n-1})\) (all its coordinates are strictly positive). We use \(\phi^*\) to denote this equilibrium. When \(|Q| = 1\), then the equilibrium is one of the vertices of the simplex. Finally, the cases \(1 < |Q| < n\) cover the other possible equilibria (for example, \(\phi = (3/4, 1/4, 0, \ldots, 0)\)).

Observe also that the equilibrium \(\phi^* \in \int(\Delta^{n-1})\) for the case \(0 < r < 1\) has some very interesting properties: it is unique, which means that the market is completely predictable. Moreover, if \(\bar{q}_i \geq \bar{q}_j\), then \(\phi_i^* \geq \phi_j^*\), which endows the market with a basic notion of fairness. Finally, the market is not a monopoly: all the market shares are strictly positive for the equilibrium \(\phi^*\).

Our next result characterises the ICT of the continuous dynamics. We start with a useful lemma which indicates that submarkets can also be modelled as RMAs.

**Lemma 5.2.** Consider a T-O market defined by \(n\) items and the submarket obtained by considering only \(n-1\) items. Then this submarket can also be modelled by an RMA.

**Proof.** Let \(\Phi^* = \{\phi_1^*, \phi_2^*, \ldots, \phi_n^*\}\) be the market share for the \(n\)-item T-O market at stage \(t\). Consider a new process \(\Psi^t\) consisting of \(n-1\) products only. We show that this process can also be modelled as a RMA. The key is to prove that the purchasing of \(p_i^t\) in stage \(t\) follows Eq. (4). Consider any item \(i \in \{1, \ldots, n\}\) such that \(\phi_i^* \neq 1\). Without loss of generality, assume that \(i = n\). Define
\[
\psi_i^t = \frac{\phi_i^t}{1 - \phi_n^t}, \quad (i < n),
\]
and consider the following events:
- \(A\) = \{product \(n\) is not purchased at stage \(t\)\}
- \(B\) = \{product \(j \neq n\) is purchased at stage \(t\)\}.
\[
e^{(1-r)\frac{1}{q_i}}(\phi_i^1)^{1-r} - \frac{q_i}{q_j}(\phi_j^0)^{1-r} = e^{(1-r)\frac{1}{q_j}}(\phi_j^1)^{1-r} - \frac{q_j}{q_i}(\phi_i^0)^{1-r}
\]

and hence
\[
\frac{(\phi_i^1)^{1-r}}{q_i} - \frac{(\phi_j^1)^{1-r}}{q_j} = e^{(r-1)\frac{1}{q_i}} \left[ \frac{(\phi_i^0)^{1-r}}{q_i} - \frac{(\phi_j^0)^{1-r}}{q_j} \right].
\]

Consider Eq. (14):

- If, for some \(i \neq j\), \(\frac{(\phi_i^1)^{1-r}}{q_i} = \frac{(\phi_j^1)^{1-r}}{q_j}\), then \(\frac{(\phi_i^1)^{1-r}}{q_i} = \frac{(\phi_j^1)^{1-r}}{q_j}\) for all \(r\);
- If \(\frac{(\phi_i^1)^{1-r}}{q_i} \neq \frac{(\phi_j^1)^{1-r}}{q_j}\), then the right-hand side of Eq. (14) goes to zero as \(t \to \infty\) (because \(r < 1\)) and hence the left-hand side of (14) also goes to zero:
\[
\lim_{t \to \infty} \frac{(\phi_i^1)^{1-r}}{q_i} - \frac{(\phi_j^1)^{1-r}}{q_j} = 0.
\]

We now prove by induction that the limits for the market shares exist. Consider the case \(k = 2\) products. Since \(\phi_2^1 = (1 - \phi_1^1)\), the market is completely characterised by the value of \(\phi_1^1\) and hence we can use a one-dimensional RMA and, by Theorem 1 in Renlund (2010), the RMA converges since \(F(x) = p(x) - x\) is a continuous function and \(\phi_2^1\) is bounded. Assume now that a RMA with \(k - 1\) products converges and consider a market with \(k\) products. By Lemma 5.2, given a \(k\)-dimensional RMA \(\Phi^t = [\phi_1^t, \phi_2^t, \ldots, \phi_k^t]\), we can create a \((k-1)\)-dimensional RMA \(\{\psi_i^t\}_{i < k}\) by defining \(\psi_i^t = \frac{\phi_i^t}{1 - \phi_k^t}\) \((i < k)\). By induction hypothesis, \(\psi_i = \lim_{t \to \infty} \psi_i^t\) exists for all \(i < k\) and therefore (14) is equivalent to
\[
\frac{(\phi_1^1)^{1-r}}{q_1(1 - \phi_k^1)^{1-r}} - \frac{(\psi_1^1)^{1-r}}{q_1(1 - \phi_k^1)^{1-r}} = e^{(r-1)\frac{1}{q_1}} \left[ \frac{(\phi_1^0)^{1-r}}{q_1} - \frac{(\psi_1^0)^{1-r}}{q_1} \right].
\]

Observe that, if \(\lim_{t \to \infty} \phi_1^1 = 1\), then \(\lim_{t \to \infty} \phi_1^0 = 0\) for all \(j \neq k\), and the market shares converge to one of the possible equilibria (i.e., a monopoly of the product \(k\)). Otherwise, the right-hand side of (16) goes to 0 when \(t \to \infty\) and \(\lim_{t \to \infty} \psi_i^t = 0\). Hence
\[
\lim_{t \to \infty} \frac{(\phi_i^1)^{1-r}}{q_i(1 - \phi_k^1)^{1-r}} also exists.
\]

Now denote by \(\bar{\phi}_i\) the limit of \(\phi_i^t\) for all \(i \in \{1, \ldots, n\}\). Using Eq. (15), the following equation holds for all \(i, j \in \{1, \ldots, n\}\):
\[
\frac{\phi_i^{1-r}}{q_i} = \frac{\phi_j^{1-r}}{q_j}.
\]

Observe that, if there exists \(i \in \{1, \ldots, n\}\) such that \(\phi_i = 0\). Eq. (17) implies that \(\phi_i = 0\) for all \(i\) which is impossible since they add up to 1. Hence the limit process has strictly positive components and Eq. (17) is equivalent to
\[
\phi_i^1 = \frac{\phi_i^{1-r}}{q_i^{1-r}} q_i^{1/(1-r)} = \frac{q_i^{1/(1-r)}}{\sum_{j=Q} q_j^{1/(1-r)}} q_i^{1/(1-r)} \frac{q_i^{1/(1-r)}}{\sum_{j=Q} q_j^{1/(1-r)}}
\]

which is the equation that defines \(\phi^\star\) in Theorem 5.1 (see Eq. (11)).

As a result, when \(\phi^0 \in \text{int}(\Delta^{n-1})\), the only ICT set for the ODE (12) is the equilibrium \(\phi^\star\) and, by Theorem 4.10, the RMA converges almost surely to \(\phi^\star\).

Consider now the case \(r > 1\) for which Theorem 5.1 still characterises the equilibrium. In this case, the dynamic behaviour is completely different due to the strength of the social signal. It is however possible to prove that the ICT set of the RMA \(\{\phi_i^t\}_{i \geq 0}\) consists only of equilibria.
\[ \frac{\partial F(\phi)}{\partial \phi_i} = \frac{\partial}{\partial \phi_i} \left[ \frac{\sum_{k \neq i} f(\phi_k)}{\sum_{k \neq i} \tilde{q}_k f(\phi_k)} - \phi_i \right] - 1 \]

\[ = \frac{1}{\sum_{k \neq i} \tilde{q}_k f(\phi_k)} \left[ (1 - \phi_i) \tilde{q}_i f(\phi) + \phi_i \left( \sum_{k \neq i} \tilde{q}_k f(\phi_k) \right) \right] - 1 \]

where we used that \( p_i(\phi) = \tilde{\varphi}_i \) (since \( \phi \) is an equilibrium) to move from the second to the third equality. Now, when \( f(x) = x^r \) for \( r > 1 \), \( f'(x) = r x^{r-1} \) and we have

\[ \frac{\partial F(\phi)}{\partial \phi_i} = \frac{1}{\sum_{k \neq i} \tilde{q}_k f(\phi_k)^r} \left[ (1 - \phi_i) \tilde{q}_i f(\phi) + \phi_i \left( \sum_{k \neq i} \tilde{q}_k f(\phi_k)^{r-1} \right) \right] - 1. \] (19)

If \( i \in \mathbb{N}\setminus\{Q\} \), then \( \tilde{\varphi}_i = 0 \) and \( \frac{\partial F(\phi)}{\partial \phi_i} = -1 \). If \( i \in \mathbb{Q} \), it follows that

\[ \frac{\partial F(\phi)}{\partial \phi_i} = \frac{r}{\sum_{k \neq i} \tilde{q}_k f(\phi_k)^{r-1}} \left[ (1 - \phi_i) \tilde{q}_i f(\phi) + \phi_i \left( \sum_{k \neq i} \tilde{q}_k f(\phi_k)^{r-1} \right) \right] - 1. \]

Since \( \sum_{k \neq i} \tilde{q}_k f(\phi_k)^{r-1} - 1 \), we have \( \frac{\partial F(\phi)}{\partial \phi_i} = r(1 - \phi_i + \tilde{\varphi}_i (|Q| - 1) - 1) - n. \)

**Corollary 5.6.** Under a social signal \( f(x) = x^r \), \( r > 1 \), the inner equilibrium \( \phi^* \) is unstable.

**Proof.** By Theorem 5.5, we have that \( \text{tr}(J(F(\phi^*))) = 2r[|Q| - 1] - n. \) Since \( \phi^* \) has \( n \) non-zero market shares, it follows that \( \text{tr}(J(F(\phi^*))) = 2r(n - 1) - n + r(n - 2) > 0 \), since \( r > 1 \) and \( n \geq 2 \). As a result, there exists an eigenvalue \( \lambda = \lambda(\phi^*) \) satisfying \( \text{Re}(\lambda) > 0 \). By Theorems 4.4 and 4.5, \( \phi^* \) is unstable. □

**Remark 5.7.** Theorem 5.5 can also be used to show that many other equilibria are unstable: they simply need to have enough non-zero market shares to satisfy \( 2r[|Q| - 1] > n \). Moreover, the theorem can also be used to show that, for any equilibrium \( \phi \) that is not a monopoly, there exists \( r > 1 \) that makes \( \phi \) unstable. It suffices to choose \( r > \frac{n}{2(|Q|-1)} \). For instance, if \( n = 4 \), all the equilibria but the monopoly are unstable as soon as \( r > 2 \).

### 6. Agent-based simulation results

We now report results from an agent-based simulation to highlight and complement the theoretical analysis. The agent-based simulation uses the setting from Abeliuk et al. (2015), which used a dataset to emulate an environment similar to the MusicLab. The setting consists of 50 songs with the values of qualities and policies specified in Appendix D. As mentioned in the introduction, the MusicLab is a trial-offer market where participants can try a song and then decide to download it. The generative model of the MusicLab (Krumme et al., 2012) uses the consumer choice preferences described in Section 3.

From this section and onwards, we assume that, at each period, a new customer arrives and may or may not buy a product based on the probability (quality) of the product tried. (Note that, in the earlier sections, each new period began when a product was purchased.) The reason for this change is our interest in quantifying the expected number of purchases per period, and how it changes depending on different ranking policies. We use the expected number of purchases per period as way to measure the market efficiency. This view obviously does not change any result from the previous sections.

The simulation setting. The agent-based simulation aims at emulating the MusicLab: each simulation consists of \( L \) iterations (\( L \) simulated users) and, at each iteration \( t: 0 < t < L \),

1. The simulator randomly selects a song \( i \) according to the probabilities \( p(\sigma, \phi) \), where \( \sigma \) is the ranking proposed by the policy under evaluation and \( \phi \) represents the market shares;
2. The simulator randomly determines, with probability \( q_i \), whether selected song \( i \) is downloaded. In the case of a download, the simulator increases the number of downloads of song \( i \), i.e., \( d_i^{t+1} = d_i^t + 1 \), changing the market shares. Otherwise, \( d_i^{t+1} = d_i^t \).

Every \( t \geq 0 \) iterations, a new list \( \sigma \) may be recomputed if the ranking policy is dynamic (e.g., the popularity ranking). In this paper, the simulation setting focuses mostly on two policies for ranking the songs:

- The quality ranking (Q-rank) that assigns the songs in decreasing order of quality to the positions in decreasing order of visibility (i.e., the highest quality song is assigned to the position with the highest visibility and so on);
- The popularity ranking (D-rank) that assigns the songs in decreasing order of popularity (i.e., \( d_i^t \)) to the positions in decreasing order of visibility (i.e., the most popular song is assigned to the position with the highest visibility and so on).

Note that the popularity ranking was used in the original MusicLab, while the quality ranking is a static policy: the ranking remains the same for the entire simulation. The simulation setting, which aims at being close to the MusicLab experiments, consider 50 songs and simulations with \( L = 10^3 \) iterations unless stated otherwise. The songs are displayed in a single column. The analysis in Krumme et al. (2012) indicated that participants are more likely to try songs higher in the list. More precisely, the visibility decreases with the list position, except for a slight increase at the bottom positions. Fig. 1 depicts the visibility profile based on these guidelines, which is used in all computational experiments.
The paper also uses two settings for the quality and appeal of each song, which are depicted in Fig. 2. In the first setting, the quality and the appeal were chosen independently according to a Gaussian distribution normalised to fit between 0 and 1. The second setting explores an extreme case where the appeal is anti-correlated with quality: the quality is the same as in the first setting but the appeal is chosen such that the sum of appeal and quality is 1.

6.1. Convergence

We first illustrate the convergence of the market for various popularity signals \([r < 1]\) using the quality ranking. In order to visualise the results, we focus on only 5 songs, where the qualities, appeals, and visibilities are given by

\[
q = [0.80, 0.72, 0.68, 0.65, 0.60] \\
a = [0.38, 0.35, 0.46, 0.27, 0.62] \\
v = [0.80, 0.75, 0.69, 0.62, 0.58].
\]

The simulation is run for \(10^5\) iterations for the social signals \(f(x) = x^r\) \((r \in \{0.1, 0.25, 0.5, 0.75\})\) and Fig. 3 depicts the simulation results. Observe that the equilibrium \(\phi^*\) (dashed lines) changes because it depends on the value of \(r\). Interestingly, for social signals with \(r \leq 0.5\), the convergence of the process seems to occur around \(10^4\) time steps (iterations) even when they start with a strong initial distortion due to the appeals of the songs. The simulations show clear differences in behaviour depending on \(r\) and, when \(r\) moves closer to 1, the market tends to exhibit a monopolistic behaviour for the song with the best quality (confirming the results obtained in Hentenryck et al. (2016)).

Fig. 4 shows how the market is distributed in the equilibrium among 6 songs. The qualities, appeals, and visibilities are given by

\[
q = [0.80, 0.72, 0.65, 0.57, 0.52, 0.49] \\
a = [0.38, 0.36, 0.27, 0.60, 0.77, 0.78] \\
v = [0.80, 0.75, 0.62, 0.48, 0.40, 0.35]
\]

and the social signals are of the form \(f(x) = x^r\) \((r \in \{0.1, 0.25, 0.5, 0.75\})\). Each stacked bar represents the proportion of the market for the 6 songs for a given social signal. Songs with better qualities (i.e., the top 2 songs represented in red and yellow respectively) have larger market shares and their market shares increase with \(r\). In contrast, the market shares of the lower-quality songs (i.e., cyan and purple, respectively) decrease when \(r\) increases. These results indicate that social influence has a beneficial effect on the market: it drives customers towards the better products, while not going to a monopoly as long as \(r < 1\).

6.2. Market predictability

This section depicts the predictability of the market for various values of \(r\) and the number of downloads per song as a function of its quality. Figs. 5 and 6 depict the results for the two quality/appeal settings discussed previously. The figures display the results of 40 experiments for each setting with 1 million arrivals. Each experiment contributes 50 data points, i.e., the number of downloads for each song, and all the data points for the 40 experiments are displayed in the figures.

In the plots, the \(x\)-axis represents the song qualities and the \(y\)-axis the number of downloads. A dot at location \((q, d)\) indicates that the song with quality \(q\) had \(d\) downloads in an experiment. Obviously, there can be several dots at the same location. For \(r \in \{0.5, 0.75, 1\}\), the market is highly predictable and there is little variation in the song downloads. For \(r = 1\), the market converges to a monopoly for the song of highest quality, confirming the results from Abeliuk et al. (2015), Hentenryck et al. (2016). Finally, for \(r = 1.25\), the market exhibits significant unpredictability, as suggested by the theoretical results. In this case, the equilibria are monopolies for various songs but it is hard to predict which song will dominate the market.

Note also that the unpredictability of the market increases significantly for \(r = 1.25\) when the appeal and quality of the songs are anti-correlated. This is not the case for \(r \in \{0.5, 0.75\}\). To evaluate the statistical significance of these results, we measure the market unpredictability as suggested by Salganik et al. (2006). The unpredictability \(u_i\) for product \(i\) is defined as the average difference in market share for that product over the 40 experiments:
where $\phi_{i,w}$ is the final market share of product $i$ in experiment $w$. We then computed the overall unpredictability for each social signal $r \in \{0.5, 0.75, 1, 1.25\}$: $U = \frac{1}{n} \sum_{i=1}^{n} |u_i|$, \( u_i = \frac{1}{\binom{40}{2}} \sum_{w=1}^{40} \sum_{w'=w+1}^{40} |\phi_{i,w} - \phi_{i,w'}| \).

Fig. 7 shows the average unpredictability $U$ and the standard deviation for the different social signals, using the same data as in Figs. 5 and 6 (Fig. 7(a) and (b) respectively). We also performed Mann–Whitney $U$ tests, comparing the values of $U$ for pairs of social signals. In all cases, a social signal $r < 1$ is significantly more predictable than the signal $r = 1.25$ ($p$-value < .05). Comparisons between $r = 0.5$ and $r = 0.75$ and $r = 0.75$ and $r = 1$ also show statistically significant differences in unpredictability. For instance, for the anti-correlated setting, the $p$-values for the various pairwise comparisons (first column is less predictable than second column) are given in Table 1

For the independent setting, Table 2 shows the pairwise comparisons that are also statistically significant in that case:

Fig. 8 compares the predictability of Q-rank and D-rank for the first setting of Quality/Appeal. For each ranking, two different social signals were used ($r = 0.5$ and $r = 1$) and the figure displays the result of 50 experiments, consisting in 1 million iterations. Two phenomena can be observed. First, sublinear signals seem to help
the D-rank, making the outcome less chaotic (first column). Second, Q-rank clearly performs better than D-rank and exhibits much less unpredictability.

6.3. Performance of the market

Figs. 9 and 10 report results about the performance of the markets as a function of the social influence signals. The figures report the average number of downloads over time among 50 experiments, for the quality and popularity rankings as a function of the social signals. There are a few observations that deserve mention.

1. For the quality ranking, the expected number of downloads increases with the strength of the social signal as \( r \) approaches 1. The equilibrium when \( r = 1 \) is optimal asymptotically and assigns the entire market share to the song of highest quality. When \( r = 2 \), the situation is more complicated. The figure shows that the market efficiency can further improve if \( r = 2 \). However, when the simulation is run for more iterations (a result not shown in the figure), the market efficiency decreases slightly compared to \( r = 1 \), which is consistent with the theory since there is no guarantee that the monopoly for \( r > 1 \) is for the song of highest quality.

2. The popularity ranking is always dominated by the quality ranking and the benefits of the quality ranking increase as \( r \) approaches 1 from below.

3. The popularity ranking in the second setting when \( r = 2 \), obtains nearly a third of the expected downloads than the quality ranking.

7. Additional observations on sublinear social signals

7.1. The benefits of social influence

A linear social signal has been shown to be beneficial to the market efficiency, i.e. it maximises the expected number of downloads. This result was proved by Abeliuk et al. (2015) for the performance ranking and by Hentenryck et al. (2016) for any static ranking such as the quality ranking. Unfortunately, sublinear social signals are not always beneficial to the market in that sense, as one can see in Example 7.1. Consider, once again, the quality ranking and assume that \( q_1 \geq \cdots \geq q_n \). When there is no social signal, by following the idea in Eq. (3) and taking \( f(\phi_i) = \beta \phi_i + \alpha a_i \), with \( \beta = 0 \), the probability of trying product \( i \) is given by

\[
p_i^* = \frac{\nu_i q_i}{\sum_{j=1}^n v_j q_j}.
\]

In this case, the expected number of purchases per period is

\[
\sum_{i=1}^n p_i^* q_i.
\]

On the other hand, with a social signal, the probability of trying product \( i \) at time \( t \) is

\[
P_t(\phi^t) = \frac{\nu_i f(\phi^t_i)}{\sum_{j=1}^n v_j f(\phi^t_j)}
\]

and the expected number of purchases per period at the equilibrium is given by

\[
\sum_{i=1}^n P_t(\phi^*) q_i = \sum_{i=1}^n \nu_i q_i f(\phi^*_i) / \sum_{j=1}^n v_j f(\phi^*_j).
\]
The following example shows that, under a sublinear social signal, the expected number of purchases (per period) at equilibrium, i.e., \( \sum_{i=1}^{n} R_i(\phi^*) q_i \), can be lower than the expected number of purchases when no social signal is used, i.e., \( \sum_{i=1}^{n} p_i q_i \).

**Example 7.1.** Consider a 2-dimensional T-O market with social signal \( f(x) = x^{0.5} \), where the qualities, visibilities, and appeals are given by

- \( q_1 = 1, q_2 = 0.4 \).
- \( v_1 = 1, v_2 = 1 \).
- \( a_1 = 1, a_2 = 0.3 \).

The expected number of purchases at equilibrium for the case with social signal is given by

\[
\frac{v_1 q_1 (\phi_1^*)^2 + v_2 q_2 (\phi_2^*)^2}{v_1 (\phi_1^*)^2 + v_2 (\phi_2^*)^2} = \frac{v_1 q_1 (v_1 q_1)^{r/(1-r)} + v_2 q_2 (v_2 q_2)^{r/(1-r)}}{v_1 (v_1 q_1)^{r/(1-r)} + v_2 (v_2 q_2)^{r/(1-r)}} = \frac{1 + (0.4)^2}{1 + 0.4} \sim 0.83.
\]

while, for the case without social signal, it is given by

\[
\frac{v_1 q_1 a_1 + v_2 q_2 a_2}{v_1 a_1 + v_2 a_2} = \frac{1 + 0.3(0.4)}{1 + 0.3} \sim 0.86.
\]

This simple example, in which the qualities and appeals are positively correlated, shows that if customers follow a sublinear social influence signal \( r = 0.5 \), the market efficiency gets reduced by around 3% (with respect to not showing them the social signal). In contrast, when \( r = 1 \), social influence drives the market towards a monopoly, which leads to an asymptotically optimal market that assigns the entire market share to the highest quality product (which may be undesirable in practice). Note that, once the qualities and appeals have been recovered (using, say, Bernoulli sampling as suggested in Abeliuk et al., 2015), one could potentially decide whether to use the social influence (in case it is sublinear \( r < 1 \)): simply compare the expected number of purchases in both settings, using the equilibrium for the social influence case and the formula for the case with no social signal.

### 7.2. Optimality of the Quality Ranking

When \( r = 1 \), it has been shown that the quality ranking is optimal asymptotically: it maximises the expected number of purchases (Hentenryck et al., 2016). If another static ordering is used, the market will converge to the product that has the highest quality when scaled by its visibility. However, when \( 0 < r < 1 \), the quality ranking is no longer guaranteed to be optimal asymptotically.

**Example 7.2.** Consider a 3-dimensional T-O market with a social signal \( f(x) = x^r, r = 0.3 \), and the following values for qualities and visibilities:

- \( q_1 = 1, q_2 = 0.261, q_3 = 0.002 \)
- \( v_1 = 1, v_2 = 0.720, v_3 = 0.229 \)
then, using quality ranking we would end up with an expected number of purchases at equilibrium, given by

\[ \sum_{i=1}^{n} P_i(\phi^*)q_i = \frac{v_1q_1(v_1q_1)^{r/(1-r)} + v_2q_2(v_2q_2)^{r/(1-r)} + v_3q_3(v_3q_3)^{r/(1-r)}}{v_1(v_1q_1)^{r/(1-r)} + v_2(v_2q_2)^{r/(1-r)} + v_3(v_3q_3)^{r/(1-r)}} \]

\[ = \frac{1 + (0.720 \times 0.261)^{10/7} + (0.229 \times 0.002)^{10/7}}{0.720(0.720 \times 0.261)^{10/7} + 0.229(0.229 \times 0.002)^{10/7}} \]

\[ \approx 0.8026. \]

The intuition behind the previous example is that if there exists a product which is much better than the rest, the best decision is to exhibit it in the first position and place, in the second position, the lowest quality product to make the first product is even more appealing. It is an open problem to determine whether there is a polynomial-time algorithm to find an optimal ranking.

8. Discussion and conclusion

This paper studied the role of social influence in trial-offer markets where customer preferences are modelled by a generalisation of a multinomial logit. In this model, both position bias and social influence impact the products tried by consumers.

The main result of the paper is to show that trial-offer markets, when the ranking of the products is fixed, converge to a unique equilibrium for sublinear social signals of the form $\phi_i^r$. Where $\phi_i$ represents the cumulative market share of product $i$. Of particular interest is the fact that the equilibrium does not depend on the initial conditions, e.g., the product appeals, but only depends on the product qualities. Moreover, when the products are ranked by quality, i.e., the best products are assigned the highest visibilities, the equilibrium is such that the better products receive the largest market shares, which increase as $r$ increases for the best products (as long as $r < 1$). The equilibrium for a sublinear social signal contrasts with the case with $r = 1$, where the market goes...
Fig. 7. Average unpredictability (grey bars), using social signals \( f(x) = x^r \), \( r \in \{0.5, 0.75, 1, 2.5\} \). (a) shows the results for the independent setting, and (b) for the anti-correlated setting. Both cases consist of 40 experiments with 1 million iterations each. Blue lines represent the respective standard deviations. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Fig. 8. Distribution of purchases versus product qualities for 50 experiments with 1 million users. (a) and (b) use a social signal \( f(x) = x^{0.5} \). (a) shows the results for the popularity ranking and (b) for the quality ranking. (c) and (d) use the social signal \( f(x) = x \). (c) shows the results for the popularity ranking and (d) for the quality ranking.
to a monopoly for the highest quality product (under the quality ranking). In the sublinear case, the market shares reflect product quality but no product becomes a monopoly. The paper also shows that, when \( r > 1 \), the market becomes more unpredictable. In particular, the inner equilibrium, which assigns a positive market share to all products, is unstable and the market is likely to converge to a monopoly for some product. However, which product becomes the monopoly depends on the initial conditions.

Simulation results on a setting close to the original MusicLab complemented the theoretical results. They show that the market converges quickly to the equilibrium for a sublinear social signal and that the convergence speed depends on the social
signal strength. The simulation results also illustrate how the market shares of the highest (resp. lowest) quality products increase (resp. decrease) with \( r \). As expected, when \( r \leq 1 \), the market is shown to be highly predictable, while it exhibits a lot of randomness when \( r > 1 \). The simulation results also show the benefits of social influence for market efficiency, and demonstrate that the quality ranking once again outperforms the popularity ranking.

Overall, these results shed a new light on the role of social influence in trial-offer markets and provide a comprehensive overview of the choices and tradeoffs available to firms interested in optimising their markets with social influence. In particular, they show that social influence does not necessarily make markets unpredictable and is typically beneficial when the social signal is not too strong. Moreover, ranking the products by quality

Fig. 10. The average number of downloads over time for the quality and popularity rankings for various social signals in the second setting for song appeal and quality.
appears to be a much more effective policy than ranking products by popularity which may induce unpredictability and market inefficiency. The results also show that sublinear social signals give decision makers the ability to trade market efficiency for more balanced market shares.

Perhaps, the main contribution of this paper is to show that markets under social influence are very sensitive to various design choices. The findings in Salganik et al. (2006) used the popularity ranking, which significantly affected their conclusions about market unpredictability and efficiency. The theoretical and simulation results of this paper, together with those in Abeliuk et al. (2015), Hentenryck et al. (2016) for the case \( r = 1 \), show that the market is highly predictable when using any static ranking and \( r \leq 1 \). Moreover, the quality ranking is optimal asymptotically when \( r = 1 \) and dominates the popularity ranking in all our simulations which were modelled after the MusicLab. This does not diminish the value of the results by Salganik et al. (2006) who isolated potential pathologies linked to social influence. But this paper shows that these pathologies are not inherent to the market but are a consequence of specific design choices in the experiment: the strength of the social signal and the ranking policy. Interestingly, it is only for a linear social signal that social influence can be shown to be always beneficial in expectation. Fortunately, for sublinear social signals, we can determine a priori if social influence is beneficial, given the analytic form of the equilibrium.

There are at least two potential research directions following this paper that worth investigating. First, it would be extremely valuable to construct large-scale cultural market experiment, varying the strengths of the social signal to complement our simulation results. Second, it would be interesting to extend our results to other settings including assortment problems (where the firm can select not only how to rank products but also which ones should be shown) (Abeliuk et al., 2016) and to classical cascade models with a social signal (Wang, Chen, & Wang, 2012).

Thanks are due to three anonymous referees for their valuable comments.

Appendix A. Key results from Benaim (1999)

Consider the set of solutions of the differential equation (9), we say that \( \mathcal{Y} = \{ \mathcal{Y}_t \}_{t \in \mathbb{R}} \) is the flow induced by the vector field \( F \), where \( \mathcal{Y}_t \) are the local unique solutions of (9) with \( x^0 = x_0 \in \Delta^{n-1} \). Benaim defines the following useful concept: A continuous function \( X : \mathbb{R}_+ \rightarrow \mathbb{R}^n \) is an Asymptotic pseudo-trajectory for \( \mathcal{Y} \) if for any \( T > 0 \)

\[
\lim_{t \rightarrow T} \sup_{0 \leq h \leq \tau} \text{dist}(X(t + h), \mathcal{Y}_h(X(t))) = 0.
\]

Recall now that our Robbins–Monro Algorithm (8) is defined by

\[
\phi^{k+1} = \phi^k + \gamma^{k+1} (F(\phi^k) + U^{k+1}).
\]

Let \( t_k = \sum_{i=1}^{k} \gamma^i \) and \( t_0 = 0 \) and define the affine interpolated process \( Z(t) \):

\[
Z(t) = \phi^k + [t - t_k] \frac{\phi^{k+1} - \phi^k}{\gamma^{k+1}}, \quad t_k \geq t \geq t_{k+1}.
\]

Consider also the map \( m : \mathbb{R}_+ \rightarrow \mathbb{N} \) defined by \( m(t) = \sup\{ k \geq 0 : t \geq t_k \} \).

Proposition A.1 (Proposition 4.1 in Benaim, 1999). Let \( F \) be a bounded locally Lipschitz vector field. Assume that

\[
&\text{A.1. For all } T > 0, \quad \lim_{k \rightarrow \infty} \sup_{t \in [0, T]} \| \gamma^{k+1} U^{k+1} \| = 0.
&\text{A.2. Suppose } \| \phi^k \| < \infty.
\]

Then the interpolated process \( Z(t) \) is an asymptotic pseudotrajectory of the flow induced by \( F \).

Proposition A.2 (Proposition 4.2 in Benaim, 1999). Let \( \phi^k \) be the Robbins–Monro Algorithm (8). Suppose that, for some \( q \geq 2 \),

\[
\sup_k \mathbb{E}(\| U^{k+1} \|^q) < \infty,
\]

and

\[
\sum_k \gamma^{k+1} q^k < \infty.
\]

Then assumption A.1 of Proposition A.1 holds with probability 1.

Let \( X : \mathbb{R}_+ \rightarrow \mathbb{R}^n \) be an asymptotic pseudotrajectory of an induced flow \( \Phi \), with \( M \) some metric space. The limit set \( L(X) \) of \( X \) is the set of limits of convergent sequences \( X(t_k) \), \( t_k \rightarrow \infty \).

Theorem A.3 (Theorem 5.7 in Benaim, 1999). Let \( X \) be a precompact asymptotic pseudotrajectory of \( \Phi \). Then \( L(X) \) is Internally Chain Transitive.

Appendix B. Proofs

Proof of Lemma 3.1. The probability that item \( i \) is purchased in the first step is given by

\[
p_i^{1st}(\phi) = \frac{\nu_i f(\phi_i)}{\sum_{j=1}^n \nu_j f(\phi_j)} q_i.
\]

The probability that item \( i \) is purchased in the second step and no item was purchased in the first step is given by

\[
p_i^{2nd}(\phi) = \left( \frac{\sum_{j=1}^n \nu_j f(\phi_j)(1 - q_j)}{\sum_{j=1}^n \nu_j f(\phi_j)} \right) \frac{\nu_i f(\phi_i)}{\sum_{j=1}^n \nu_j f(\phi_j)} q_i.
\]

More generally, the probability that item \( i \) is purchased in step \( m \) while no item was purchased in earlier steps is given by

\[
p_i^{mth}(\phi) = \left( \frac{\nu_i f(\phi_i)}{\sum_{j=1}^n \nu_j f(\phi_j)} \right) m^{-1} \frac{\nu_i f(\phi_i)}{\sum_{j=1}^n \nu_j f(\phi_j)} q_i.
\]

Let \( a = \left( \sum_{j=1}^n \nu_j f(\phi_j) q_j \right) \left( \sum_{j=1}^n \nu_j f(\phi_j) \right)^{-1} \). Observe that, if \( q_{\max} = \max_{i=1, \ldots, n} q_i \), then \( 0 < a \leq q_{\max} \leq 1 \). Eq. (21) becomes

\[
p_i^{mth}(\phi) = (1 - a)^{m-1} \frac{\nu_i f(\phi_i)}{\sum_{j=1}^n \nu_j f(\phi_j)} q_i.
\]

Hence the probability that the next purchase is item \( i \) is given by

\[
p_i(\phi) = \sum_{m=0}^{\infty} (1 - a)^m \frac{\nu_i f(\phi_i)}{\sum_{j=1}^n \nu_j f(\phi_j)} q_i.
\]
Since \(|1 - a| < 1\), we use the geometric series
\[
\sum_{m=0}^{\infty} \left(1 - a\right)^m = \frac{1}{a},
\]
and then, the probability that the next purchase is item \(i\) is given by
\[
p_i(\phi) = \frac{v_i q_i f(\phi_i)}{\sum_{j=1}^{p} v_j q_j f(\phi_j)}. \quad \square
\]

Proof Theorem 4.10. Thanks to H1 – H2. Proposition A.2 holds for \(q = 2\). As a result, we can apply Proposition A.1 and \(Z(t)\) from Eq. (20) is almost surely an asymptotic pseudo-trajectory for the flow induced by \(F\). As \(x' \in \Delta^{n-1}\), then \(Z(t)\) is precompact. Finally, using Theorem A.3, the limit set \(L(x')_{t \geq 0}\) is an ICT for Eq. (9). \(\square

Appendix C. Market shares versus purchases

The condition \(d_0 = a\) can be relaxed and the results still hold but the notations become more complicated. Indeed, define the variables \(\mu_i = \frac{n \cdot d_i}{\sum_{j=1}^{n} d_j}\), with \(a = \sum_{i=1}^{n} a_i\), the cumulative appeal, and \(\mathbf{a}, \mathbf{d}\) the vectors of appeals and purchases respectively. By definition \(\sum_{j=1}^{n} d_j = k\), then we can define the probability function \(p(\mu^{k})\) by
\[
p_i(\mu^k) = \frac{v_i q_i f(\mu^k)}{\sum_{j=1}^{n} v_j q_j f(\mu^k)}, \quad i \in \{1, \ldots, n\}
\]
and recover a recurrence for \(\mu\) as follows:
\[
\mu^{k+1} = \frac{\mathbf{a} + \mathbf{d}^k}{\mathbf{a} + k} = \frac{\mathbf{a} + \mathbf{d}^k}{\mathbf{a} + k + 1} + \frac{e^k}{\mathbf{a} + k + 1} = \mu^k \left(1 + \frac{1}{\mathbf{a} + k + 1}\right).
\]
In consequence, all the results from this paper can be translated from the \(\phi\) domain to the \(\mu\) domain.

Appendix D. Dataset

Table 3 shows the values of the qualities and appeal for the independent setting (obtained from Abeliul et al., 2015). Table 4 shows the values of the visibilities for each position \(j \in \{1, \ldots, n\}\).
